The funniest anime season of all time is coming back... this time with a heart.Ultrasound-assisted catheterization and peripheral intravascular catheterization procedures: a systematic review. The aim of the present study was to summarize available evidence of ultrasound (US)-assisted peripheral intravenous (IV) catheterization for catheterization procedures, including a systematic review of the current state of knowledge related to critical clinical aspects. Electronic databases from inception to December 2014 (CINAHL, Embase, Medline, PEDro, and the Cochrane Library) were systematically searched for articles describing US-assisted catheterization procedures. Primary outcomes were success, pain, and complications (femoral, jugular, and other). Secondary outcomes were adverse events (myocardial infarction, stroke, and thromboembolic events), time duration, and success rates for different types of instruments. Out of 3997 titles, 227 articles were included and were graded using the PEDro scale. Twenty-two articles met the inclusion criteria for the systematic review. The majority of the studies were grade B (n = 15; 68.2%), and sample size was grade B (n = 17; 77.3%). The most common procedures performed were central venous catheterization (n = 14), peripheral IV cannulation (n = 10), and femoral vein catheterization (n = 6). The majority of the included studies reported success rates and adverse events, and time duration of the different procedures. The use of US-assisted catheterization to perform peripheral IV catheterization was found to be safe. The addition of US did not increase the success rates, but did reduce the duration of the procedure. The use of US-assisted peripheral IV

catheterization should be considered as a potential alternative to fluoroscopy.
